Abstract

We examine empirically the relationship between the extent of redistribution and the components of the Mirrlees framework, with a focus on inherent inequality and government’s redistributive preferences. We have constructed our income distribution variables from the Luxembourg Income Study (LIS) database, which provides information on both factor and disposable incomes. Our redistributive preference measure is constructed using the optimal tax formula for which we have collected data from various sources. In addition to traditional linear specifications, we use flexible methods to allow nonlinearities because pre-specified functional forms are not easy to justify in empirical investigations of the optimal tax framework. We study 14 advanced countries for approximately four decades and find support for the Mirrlees model: There is a positive relationship between factor-income inequality and the extent of redistribution. We also find a link between our redistributive-preference measure and the extent of redistribution.

Keywords: income inequality, nonlinearity, preferences, redistribution

JEL classification: C14, D31, H3

The authors wish to thank Vidar Christiansen, Thomas Gaube, Emmanuel Saez, Håkan Selin, Danny Yagan and participants at the Seventh ECINEQ Meeting for useful comments on an earlier version of this study. Funding from the Strategic Research Council (SRC) at the Academy of Finland (project no. 293120, ‘Work, Inequality and Public Policy’) is gratefully acknowledged.

1. Introduction

The post-war history of income inequality in advanced countries can be divided, at least roughly, into two phases. From 1945 to about the mid-1980s, pre-tax inequality, or the inequality of factor incomes (incomes from earnings and capital), decreased at least in part because of a reduction in skilled/unskilled wage differentials and asset inequality. The second phase occurred from the 1980s onward, when inequality reversed course and increased. For the 1970s and the above-described latter period we have evidence from the Luxembourg Income Study (LIS) database. This database provides data on both factor and disposable incomes for a number of advanced countries over the past four decades, which facilitates the study of the extent of redistribution. The difference between the factor-income Gini and disposable-income Gini is an often-used measure of the overall redistributive effect of taxes and transfers. These types of difference measures are also used in the current study to discuss the evolution of the extent of redistribution.

For example, Immervoll and Richardson (2011) studied OECD countries using the LIS data. They reported that governmental redistribution has become less effective in compensating increasing inequalities since the 1990s. Moreover, top income shares have increased in many advanced economies over the past three decades (Atkinson & Piketty, 2010), and top tax rates on upper-income earners have declined significantly in many OECD countries during this period (Piketty et al., 2014). Economists have formulated several hypotheses about the causes of increasing inequality, but the explanations are not fully compelling. For example, Atkinson et al. (2011) emphasised that it is very difficult to account for these figures using the standard labour supply/demand explanation. Hence, the role of social policies and progressive taxation should not be dismissed in these discussions.

Figure 1 illustrates changes that have taken place in factor-income inequality and redistribution during a period of 20 years, from the mid-1980s to the mid-2000s. The figure implies a positive association, but there are some outliers. For example, in France inequality decreased during this period, but there was more redistribution. Thus, it seems that factor-income inequality does not fully explain the extent of redistribution in the plotted countries.

There is now a considerable body of empirical literature seeking to explain the observed patterns of redistribution. Here we outline some of this literature. The starting
Figure 1: Illustration of evolution from the mid-1980s to the mid-2000s: we plot the change in factor-income Gini against the change in the extent of redistribution over this period; change is defined as the difference between two observations. The Gini coefficients are expressed as percentages, and the extent of redistribution is defined as $RD_{relative} = 100(Gini_{factor} - Gini_{disposable})/Gini_{factor}$. The corresponding factor-income Ginis of the 14 countries are provided in Table 1. Data source is the LIS database, and more information can be found in Appendix A.

Point for seeking the determinants of the extent of redistribution, both across countries and over time, is most commonly some model of the political process, originating with Romer (1975), Roberts (1977) and Meltzer and Richard (1981). Persson and Tabellini (2002) provide a survey. A key element in this literature is the political mechanism – the median voter theory – through which greater inherent inequality leads to greater redistribution. The often-cited model of Meltzer and Richard (1981) shows that the larger the gap between mean and median income (that is, inequality), the larger the scale is of income redistribution favoured by the median voter. However, some authors have suggested that redistribution is greater the less inherent inequality there is (e.g. Peltzman, 1980; Persson, 1995; Lindert, 2000). Peltzman (1980) attempts an explanation that greater inequality links to the lower classes’ ability to demand redistribution towards themselves.

Empirical studies have provided mixed evidence on the association between inequality and demand for redistribution (e.g. Perotti, 1996; Moene & Wallerstein, 2001; Finseraas, 2009). For example, Alesina et al. (2001) provided a distinct example of the ‘paradox of redistribution’: a simple comparison of the United States and Europe showed that Europe had lower pre-tax inequality and more redistribution. They pointed out that the extent of altruism – which may be different in different societies – may show in the demand for redistribution. In addition, Georgiadis and Manning (2012) showed that implications
resembling altruism may arise when individuals are uncertain about their future incomes – thus, individuals may be concerned about tax rates at different points in the distribution. Earlier, Benabou and Ok (2001) discussed the ‘prospect of upward mobility’ hypothesis – individuals may consider outcomes in those parts of the income distribution where they expect to end up in the future.

Numerous recent empirical studies on inequality and redistribution have utilised the LIS database. For example, both Milanovic (2000) and Scervini (2012) confirmed the positive association between inequality and redistribution, but Milanovic (2000) found less support for the median voter hypothesis in explaining redistribution decisions. Milanovic (2010) discusses the critique that his earlier study has received and, in particular, emphasises the median voter hypothesis as only one possible mechanism between initial inequality and redistribution. Recently, Luebker (2014) emphasised behavioural aspects in understanding the extent of redistribution. He did not find support for the Meltzer–Richard hypothesis, but he provided some evidence that actual preferences are associated with redistributive outcomes.

The approach in this study is novel and different from those above because our starting point is the optimal tax framework developed by Mirrlees (1971). The Mirrlees model has dominated the economics of redistributive taxation for the past 40 years, and three elements of the model are useful for our purpose. First is the concept of inherent inequality, reflecting, among other things, skilled/unskilled wage differentials, asset inequality and social norms. If there is no intervention by the government, the inherent inequality will be fully reflected in the disposable income. However, if the government wants to intervene – as seems to be the case in developed countries – it will find the second component of the Mirrlees model, the egalitarian objectives of the government. In addition, if the government tries to redistribute income from high-income people to low-income people, there will be incentive and disincentive effects. In other words, redistribution policy is a product of circumstances and objectives.

Kanbur and Tuomala (1994) showed that the optimal income tax/transfer system becomes more progressive when inherent inequality increases, taxing the better off at higher rates to support the less well off. Thus, one of the policy responses in view of inherent inequality should be a greater willingness to redistribute through the tax and transfer system. Correspondingly, if inherent inequality decreases, governmental redistribution
The Mirrlees (1971) model treats differences in observed income as being due to un-
observed differences in ability, which means that individuals know exactly what income
they will receive at each possible level of effort. One might well argue that people do not
owe their (un)success entirely to ability but that part of the income differentials are due
to luck. The critical question is whether differences in income come mostly from luck or
from ability. If the role of luck is significant in determining income, it is reasonable to
have progressive taxation – a form of social insurance in which the lucky subsidise the
unlucky. There is another strand of optimal redistribution literature (see Mirrlees, 1974;
Varian, 1980; Tuomala, 1990) stressing the social insurance role of redistributive taxation.
In this framework, an increase in variability of income would also increase the optimal
degree of progressivity because it increases the insurance value of progressive taxation.

Interestingly, at the same time as the large growth in top income shares over the
past few decades, many advanced countries have shifted the tax burden from the top to
further down in the distribution. Numerical results in Tuomala (2016) suggest that this
shift in tax burden cannot be justified by the standard Mirrlees model, which embodies
conventional assumptions about inequality aversion and the trade-off between equity and
efficiency. Both in utilitarian and maximin cases, an appropriate response to rising in-
equality is a shift towards a more progressive income tax system. For more details, see
Tuomala (2016).

Previously, Tanninen and Tuomala (2005) discussed how some of the basic features of
redistribution can be explained through the Mirrlees model. They examined the relation-
ship between inherent inequality and the extent of redistribution by utilising the LIS data
for a number of OECD countries over two to three decades. They found that redistrib-
ution is positively associated with inherent inequality. However, their empirical results
were based on the assumption that the degree of espoused egalitarianism has remained
constant over the period considered. There is now some recent individual-country-level
evidence that there could have been a shift in norms, causing governments to become
less willing to finance transfers and to levy progressive taxes, leading to reductions in the
extent of redistribution. One could argue, in line with Atkinson (1999), that these kinds
of changes have been episodic rather than time-trend and are therefore rather difficult to
justify, for example, in the context of median voter models. Thus, we focus here also on
the role of the egalitarian objectives of government, which is an important component of the Mirrlees model.

To the best of the authors’ knowledge, the current empirical study is the first to explore inequality, redistributive preferences and the extent of redistribution in the Mirrlees framework. The utilised LIS database provides data on both factor and disposable incomes for a number of advanced countries over the last four decades, and the current study focuses on 14 advanced economies. In addition to using Gini coefficients, we also utilise percentile ratios in measuring inequality and the extent of redistribution. Moreover, we have collected data from various sources to construct a measure of government’s taste for redistribution.

The structure of the paper is as follows. Section 2 depicts the data, empirical specification and methods. The current paper employs, in addition to traditional linear models, flexible methods to address the issue of chosen functional forms. Namely, the shapes of the relationships are not known beforehand. Section 3 provides our empirical results, including sensitivity checks. Finally, Section 4 concludes.

2. Empirical approach

2.1. Specification and data

The relationship that we test can be expressed as follows:

$$RD = h(I_f, \gamma, \epsilon; \mathbf{x}),$$

where $RD$ is the extent of redistribution measured in terms of the difference between factor-income inequality ($I_f$) and disposable-income inequality ($I_d$). Our main results are presented for a relative measure; that is, $RD_{I,\text{relative}} = 100(I_f - I_d)/I_f$. In the sensitivity analysis, we also discuss the alternative case where the extent of redistribution is measured in absolute terms. Function $h$ includes three components, $I_f$, $\gamma$ and $\epsilon$, that reflect the ingredients of the Mirrlees model, and they are inherent inequality, government’s redistributive preferences and elasticity of taxable income, respectively. In addition, $\mathbf{x}$ denotes control variables.

We begin by describing our inequality data. Most of the median voter studies have utilised data sets including the largest possible number of countries all around the world (e.g. the panel data set of Deininger and Squire, 1996). However, such data sets have
many problematic features that have been discussed in detail by Atkinson and Brandolini (2001). As Milanovic (2000) pointed out, there is no proper distinction between inherent income and redistribution (for different definitions of income see Atkinson et al., 1995). Fortunately, this distinction can be taken into account in the LIS data.

Data source: Luxembourg Income Study (LIS). More information can be found in Appendix A.
* This year’s observation cannot be used in empirical models due to missing information in other variables.

We have calculated inequality measures for two income concepts – factor and disposable household income – from the LIS database. We refer to the difference between these two measures as redistribution. LIS has harmonised microdata from (mostly) high- and middle-income countries, and the data are organised into different waves according to the date of the data. In addition to the LIS historical data (Wave 0), we use the data from Wave I around 1980 to Wave IX around 2013. The lengths of different waves are not uniform. Moreover, some countries may have more than one observation within the same wave.\(^1\) We use all available LIS data for which data on our other variables are available, and the resulting data set is not balanced.

We focus on the 14 advanced countries that are listed in Table 1. In addition to

\(^1\)For more information about the LIS waves, visit: http://www.lisdatacenter.org/our-data/lis-database/documentation/list-of-datasets/.
studying the traditional Gini coefficients, we investigate the development of the percentile ratio P90/P50. The table illustrates that over the sample period the inequality of factor incomes has risen in most countries.

Figure 2 shows the development of the extent of redistribution \((RD_{Gini; relative})\) in the countries under investigation. The countries are categorised into three groups to provide a concise but readable illustration. The categorisation is the following: Anglo-Saxon (Australia, Canada, Ireland, the UK and the USA; in main result models \(N = 44\)), Nordic (Denmark, Finland, Norway and Sweden; in main result models \(N = 20\)), and Continental European (France, Germany, the Netherlands, Italy and Spain; in main result models \(N = 41\)). The figure shows that the extent of redistribution has increased modestly in some countries. Thus, it appears that the redistributive role of government has corrected for some of the increase in inherent inequality. A corresponding figure of our alternative measure \(RD_{P90/P50; relative}\) is in Appendix B (Figure B.6).

![Figure 2](image_url)

Figure 2: Evolution of the extent of redistribution when redistribution is measured in relative terms: \(RD_{Gini; relative}\) (14 advanced countries, unbalanced data, years 1967–2013). Calculations based on LIS database. More information can be found in Appendix A.

How do we measure preferences for redistribution? There is a growing number of studies trying to reveal social or distributional preferences behind tax/transfer policy. Those studies start from the existing tax and transfers system and reverse-engineer it to obtain the underlying social preferences. Earlier contributions using this method are by
Christiansen and Jansen (1978) and Ahmad and Stern (1984). Recently, detailed micro data on incomes and corresponding marginal tax rates have become available to study the social preferences implicit in tax–benefit systems. One of the first studies using micro data was by Bourguignon and Spadaro (2012). They consider the revealed social preferences of the French tax–benefit system, considering the inverse optimal problem. Jacobs et al. (2017) use this method to find the redistributive preferences of political parties implicit in the reform proposals combining the reform proposals with micro data on the income distribution and the elasticity of the tax base in the Netherlands. Spadaro et al. (2015) in turn consider the revealed social preferences of the tax–benefit systems for all European countries using European Union Statistics on Income and Living Conditions data.

![Figure 3: Evolution of redistributive preferences (14 advanced countries, unbalanced data). In calculating the $\gamma$ (gamma) values, we have assumed constant elasticity of $\epsilon = 0.20$. Data are constructed from multiple sources, and more information is provided in Appendix A.](image)

In our empirical applications, we try to reveal government’s taste for redistribution ($\gamma$) using the optimal tax formula $\tau = (1 - \gamma)/(1 - \gamma + \alpha \epsilon) \iff \gamma = 1 - \tau \alpha \epsilon / (1 - \tau)$, where $\tau$ is top income tax rate, $\alpha$ is Pareto-Lorenz coefficient and $\epsilon$ is elasticity of taxable income (Saez, 2001). Our data on top income tax rates and Pareto-Lorenz coefficients are collected from various sources, such as Piketty et al. (2011, 2014) and the World Inequality Database (2017); see Appendix A for more detailed information. Moreover, no reliable panel data on behavioural responses $\epsilon$ exist, so we have investigated our results...
with some ‘reasonable’ values from the prior literature. In our preferred specifications we assume \( \epsilon = 0.20 \). For example, Saez et al. (2012) suggest that aggregate elasticities of taxable income are between 0.1 and 0.4. Moreover, in our empirical applications we consider only values \( \gamma \geq 0 \). This restriction to nonnegative values limits the number of observations in our empirical models: when \( \epsilon = 0.20 \), we get \( N = 105 \). Figure 3 describes the evolution of government’s taste for redistribution in the 14 countries of this study. Higher \( \gamma \) reflects lower redistributional preferences in society. According to Figure 3, government’s preferences to redistribute have decreased in many countries. In addition, we tried three alternative assumptions in calculating values for \( \gamma \): these cases were \( \epsilon = \{0.10, 0.15, 0.25\} \), and they are briefly discussed in the sensitivity checks.

Finally, our control variables are share of government employment, dependency rate, unemployment rate, trade union density and openness.\(^2\) Summary statistics and a complete list of data sources and definitions are provided in Appendix A.

2.2. Estimation method

We do not impose linearity into all our empirical models. In our preferred specifications, we allow all continuous covariates to enter flexibly so that potentially wrong functional forms would not bias our results. Our estimation approach is based on penalized cubic regression splines although we acknowledge that there are numerous alternative approaches to flexible modelling, such as kernel estimation.\(^3\) Moreover, due to small sample size, we assume an additive structure instead of a fully nonparametric one.\(^4\) The chosen method is accessible as there is a connection to traditional parametric models –

\(^2\)It has been argued that a larger government is ‘needed’ in more open economies. Rodrik (1998) gives an explanation that open economies are more subject to external shocks and that larger redistribution provides insurance and more stable income for individuals. In addition, the authors of the current study acknowledge that full assessment of the extent of redistribution should also take account of various publicly provided services at less than market value. These are considerable in Nordic countries. Many of these items – health care, education and social services – are very extensive.

\(^3\)Li and Racine (2006) describe nonparametric methods extensively, with the focus on kernels. Ahamada and Flachaire (2013) provide a concise overview of nonparametric methods.

\(^4\)Additive models are a special case of generalized additive models (GAMs). GAMs were introduced by Hastie and Tibshirani (1986, 1990). They present a GAM as a generalized linear model where some of the covariates can enter the model in linear form, and some terms are smooth functions of covariates. This study is restricted to a special case: it uses an identity link and assumes normality in errors, which leads to additive models.
traditional linear models are a special case. Moreover, there are ready-made statistical packages that can be utilised in the analysis. To estimate our additive models we use the established R software package ‘mgcv’, which has previously been utilised in economics studies on varying topics.\footnote{For example, Greiner and Kauermann (2008), Ordás Criado et al. (2011), Bose et al. (2012) and Berlemann et al. (2015) apply (generalized) additive models.}

Additive models provide a flexible framework for investigating the relation between inequality and redistribution. This study follows the approach presented in Wood (2006). The basic idea is that the model’s predictor is a sum of linear and smooth functions of covariates:

\[
\mathbb{E}(Y_i) = X_i^* \theta + f_1(x_{1i}) + f_2(x_{2i}) + f_3(x_{3i}) + ... 
\]

In the above presentation, \( Y_i \) is the response variable (extent of redistribution), \( X_i^* \) is a row of the model matrix for any strictly parametric model components, \( \theta \) is the corresponding parameter vector and \( f_{\cdot} \) are smooth functions of the covariates, \( x_{\cdot} \).

The flexibility of these models comes at the cost of two problems. First, one needs to represent the smooth functions \( f_{\cdot} \) in some manner. One way to represent these functions is to use cubic regression splines, which is the approach adopted in this study. A cubic regression spline is a curve constructed from sections of cubic polynomials that are joined together so that the resulting curve is continuous up to the second derivative. The points at which sections are joined (and the end points) are the knots of the spline, and these locations must be chosen. The spline can be represented in terms of its values at the knots. Second, the amount of smoothness that functions \( f_{\cdot} \) will have needs to be chosen. Overfit is to be avoided and, thus, departure from smoothness is penalized. The appropriate degree of smoothness for \( f_{\cdot} \) can be estimated from the data by, for example, maximum likelihood, which is the chosen approach in this study for its robustness.

The package ‘mgcv’ has an automatic choice in the amount of smoothing and wide functionality.\footnote{The results in this study are obtained using the package ‘mgcv’ (1.8-16), which includes a function ‘gam’. Basis construction for cubic regression splines is used. The maximum likelihood method is used in the selection of the smoothing parameters. The identifiability constraints (due to, for example, the model’s additive constant term) are taken into account by default. More details can be found in Wood (2006) and the R project’s web pages (http://cran.r-project.org/).}  The relationship between the covariates and the response can be described
graphically. Confidence bands for the model terms can be derived using Bayesian methods, and approximate $p$-values for model terms can be calculated. Models can be compared using information criteria such as the Akaike information criterion (AIC). For further details, see Appendix D and Wood (2006).

3. Results

3.1. Main results

In this subsection we provide some traditional linear models’ results (OLS with dummy variables) and compare them to more sophisticated additive models’ results. The additive models can be stated as:

$$RD_{i; relative} = \theta_0 + f_1(I_{f, it}) + f_2(\gamma_{(t), it}) + f_3(\text{government employment}_{it})$$
$$+ f_4(\text{dependency}_{it}) + f_5(\text{openness}_{it}) + f_6(\text{unemployment}_{it})$$
$$+ f_7(\text{union}_{it}) + f_8(t) + u_i + v_{it},$$

where $i$ refers to a country and $t$ to year, and $\theta_0$ is the constant term. In our main analysis, the extent of redistribution ($RD$) is studied in relative terms as we discussed in Section 2.1. Functions $f$ are smooth functions that are described using penalized cubic regression splines. Fixed country effects are denoted by $u_i$ (traditional dummy variables), and the $v_{it}$ are traditional error terms. The fixed country effects should take into account factors that stay constant over time within each country.

The additive model above describes the most flexible specification that is studied, and other specifications are special cases of it. In the traditional models all terms (functions $f$) are linear, but the additive models allow all functions $f$ to be nonlinear with no pre-specified functional form. However, the additive models may also have some linear terms if the data suggest a linear structure. Thus, linear terms are reported for the additive models if linearity was suggested in the initial stage of model fitting. In reporting our results, graphical illustrations are used for nonlinear terms. In comparison, the interpretation of linear terms is straightforward, and these terms are not plotted.

Table 2 reports our main results. The information criteria show that the additive models fit the data better than the corresponding traditional models. However, in many cases the traditional and additive models give qualitatively similar information regarding the variables of interest. First, $Gini_f$ is positively associated with the extent of redistribution.
Table 2: Results of models where the dependent variable is $RD_{I\text{,relative}}$, where $I$ refers to inequality measure. All models include country dummies and have $N = 105$. Constant terms and country fixed effects are not reported. The coefficients (and standard errors) are provided for traditional (i.e., OLS with dummies) models. The coefficients for the linear terms in the additive models are also provided to help the reader compare the models. Figure 4 shows graphical illustrations of the smooth functions that are nonlinear.

***, **, *, ' denote significance at the 1, 5, 10 and 15% levels, respectively.

Note regarding the additive models: The smooth terms' significance levels are based on approximate $p$-values.

According to approximate F-tests, the additive models are preferred to their traditional counterparts at the 5% significance level. Moreover, the approximate F-tests guide towards choosing the broadest models, (4) and (8).
Figure 4: Illustrations of the smooth functions $f$ in the additive models of Table 2. The dependent variable in models (2) and (4) is $RD_{Gini,relative}$, whereas the dependent variable in models (6) and (8) is $RD_{P90/P50,relative}$. The slopes of the functions are of interest. The plots also show the 95% confidence bands (dashed) and the covariate values as a rug plot along the horizontal axis.
(RD_{Gini;relative}), but models (2) and (4) show that the relationship may be more complex than a linear association; see the change in the slope of the function in the topmost plots, (a) and (b), in Figure 4. The percentile ratio \( P90/P50_f \) also correlates positively with the extent of redistribution in the upper half of the distribution (RD_{P90/P50;relative}). Second, the taste for redistribution (\( \gamma_e \)) is in linear, negative association to the extent of redistribution; linear association is found in all the models in Table 2. These findings accord qualitatively with the Mirrlees model. We can also see that the main results for \( I_f \) and \( \gamma_e \) are not sensitive to the inclusion of a wide range of control variables: the signs of the slopes do not change after adding controls.

Moreover, we find that government employment is statistically significantly and positively linked with the extent of redistribution; see also plots (d) and (e) in Figure 4. We also find that our empirical models are not able to capture all changes in RD_{I;relative} over time: the shape of \( f(year) \) is shown in plots (i)–(k) in Figure 4. This implies that even the broadest models, (4) and (8), do not capture all time-varying factors that relate to the extent of redistribution.

3.2. Sensitivity checks

The remainder of this section provides information about our results’ sensitivity. First, we investigate our findings’ robustness with respect to the chosen elasticity parameter. Second, we investigate the sensitivity of our findings to leaving some countries out of the sample. Third, we discuss our results when we change the specification so that the same explanatory variable (inequality measure) is not used to construct the dependent variable (redistribution). Finally, we use an alternative way to measure the extent of redistribution to check if this affects our main conclusions.

Measuring the government’s taste for redistribution (\( \gamma \)) is not an easy task, and for this reason, we tested alternative values for the elasticity (\( \epsilon \)). The above results were for the case \( \gamma_{(\epsilon=0.20)} \) (\( N = 105 \)). In our alternative models, we studied cases (a) \( \epsilon = 0.10 \) (\( N = 120 \)), (b) \( \epsilon = 0.15 \) (\( N = 114 \)) and (c) \( \epsilon = 0.25 \) (\( N = 94 \)).\(^7\) In case (c) we were left with a very small sample size, and some of our empirical results were not statistically significant. In cases (a) and (b) with lower elasticities, our main results were qualitatively

\(^7\)As the elasticity increases, the number of observations in our data set decreases. This happens because we are limited to using values \( \gamma \geq 0 \).
similar to those discussed earlier in this paper. Appendix C provides details.

Our second sensitivity check is related to the fairly small sample size. Because our main models included only 14 countries, we checked whether some groups of countries drive the main results. We did these investigations by using the specifications of Table 2, leaving each country group out of the sample (one group at a time). The countries were categorised into three groups, as in Figures 2–3. Only after dropping the Anglo-Saxon countries from the sample did we find that Gini_f was very nonlinearly linked to RD_{Gini:relative}. Otherwise, we found that our main findings on factor-income inequality and redistributive preference variables are fairly robust.

Table 3: Sensitivity checks: alternative additive model specifications. All models have N = 105. The coefficients (and standard errors) are provided for the linear terms. Figure 5 shows graphs of the reported smooth functions that are not linear.

***, **, *, ' indicate significance at the 1, 5, 10 and 15% levels, respectively.
Note: The smooth terms’ significance levels are based on approximate p-values.
All models include country dummies and the following controls (some enter the model in nonlinear form):
share of government employment, dependency rate, openness, unemployment rate, trade union density and a flexible term for year.

As a third sensitivity check, we estimated models where we did not use the same inequality indicator on both sides of the estimation equation. That is, we tested models with the alternative factor-income inequality measure. Table 3 reports two examples of these specifications, see models (9) and (10). Both models’ results are qualitatively similar to our main findings in Table 2; factor-income inequality is positively linked with redistribution, whereas \gamma is negatively associated with redistribution.

---

8To be precise, when only the Nordic and Continental European countries were included in the sample, the association between RD_{Gini:relative} and Gini_f resembled the letter M.
Figure 5: Illustration of the smooth functions $f$ in the additive models of Table 3. The plots also show the 95% confidence bands (dashed) and the covariate values as a rug plot along the horizontal axis.

Finally, we checked how our results change if the extent of redistribution is measured in absolute terms. Table 3 reports models (11) and (12) where $RD_{I;\text{absolute}} = I_f - I_d$ is the dependent variable. Again, the results are qualitatively similar to our main findings.

4. Conclusions

This paper examined the relationship between the extent of redistribution and the components of the Mirrlees model. To describe income inequality and redistribution, we used the Gini coefficients and the P90/P50 percentile ratios calculated from the LIS database. We also collected data from various other sources and constructed a measure of redistributive preferences by utilising the optimal tax formula. Instead of relying solely on linear specifications in our empirical models, we also utilised penalized spline methods to allow nonlinearities in a flexible manner. We found a positive link between inherent (factor-income) inequality and the extent of redistribution. Moreover, we found a significant association between the extent of redistribution and government’s taste for redistribution. These empirical results are qualitatively in line with the Mirrlees model.

List of data sources and definitions:

- Income inequality ($I$): $Gini_f$, $Gini_d$, $P90/P50_f$ and $P90/P50_d$ are from the Luxembourg Income Study (LIS) database (2017); subscript ‘$f$’ refers to factor incomes and ‘$d$’ to disposable incomes.

- Redistribution: calculated using the $I_f$ and $I_d$ variables (described above). Absolute measures calculated as $RD_{I, absolute} = I_f - I_d$, and relative measures calculated as $RD_{I, relative} = 100(I_f - I_d)/I_f$.

- Redistributive preference $\gamma$, using the optimal tax formula

\[
\tau = (1 - \gamma)/(1 - \gamma + \alpha \epsilon) \Leftrightarrow \gamma = 1 - \tau \alpha \epsilon/(1 - \tau).
\]

Top income tax rates ($\tau$) from Piketty et al. (2014), OECD (2017) and the Association of Finnish Local and Regional Authorities (2017): Piketty et al. data are used for years up to 2010; the OECD data are used to extend series up to 2013; as an exception, the whole Finnish series has been updated using data from the OECD and the Association of Finnish Local and Regional Authorities. Pareto coefficients ($\alpha$) are calculated using the relative shares of top 10% and top 1% income shares from the World Inequality Database (2017). These two series were available for all countries in our sample. To create longer series without breaks, we have imputed data in two cases: (1) when the top income share series begins (ends) one year later (earlier) compared to our data from the LIS database, we repeat the closest value for that year; (2) when there are at most three consecutive observations missing in the series, but we have data from the LIS database, we use linear interpolation. We assume constant elasticity and study cases $\epsilon = \{0.10, 0.15, 0.20, 0.25\}$; in our preferred specifications we assume $\epsilon = 0.20$.

• Dependency rate: share of population who are 14 years or under or 65 years or over, as per cent of total population. Source: OECD (2017).

• Openness: the sum of exports and imports as per cent of GDP. Source: OECD (2017).

• Unemployment rate as per cent of civilian labour force. Source: OECD (2017).

• Trade union density, as percentage. Source: OECD (2017).

Appendix B. Additional descriptive figure of $RD_{P90/P50}$

Figure B.6: Evolution of the extent of redistribution when redistribution is measured in relative terms: $RD_{P90/P50;relative}$ (14 advanced countries, unbalanced data, years 1967–2013). Calculations based on LIS database. More information can be found in Appendix A.
Appendix C. Sensitivity of results with respect to chosen $\epsilon$

Table C.5: Sensitivity checks: alternative values for the elasticity parameter $\epsilon$. This table provides selected results of additive model specifications. The coefficients (and standard errors) are provided for the linear terms. Figure C.7 shows graphs of the smooth functions that are not linear.

***, **, *, ‘ indicate significance at the 1, 5, 10 and 15% levels, respectively.

Note: The smooth terms’ significance levels are based on approximate $p$-values.

All models include country dummies and the following controls (some enter the model in nonlinear form): share of government employment, dependency rate, openness, unemployment rate, trade union density and a flexible term for year.

Figure C.7: Illustration of the smooth functions $f$ in the additive models of Table C.5. The plots also show the 95% confidence bands (dashed) and the covariate values as a rug plot along the horizontal axis.
Appendix D. Supplementary information about the estimation method

Consider a model containing only one smooth function of one covariate: $y_i = f(x_i) + \epsilon_i$, where $\epsilon_i$ are i.i.d. $N(0, \sigma^2)$ random variables. To estimate function $f$ here, $f$ is represented so that the model becomes a linear model. This is possible by choosing a basis, defining the space of functions of which $f$ (or a close approximation to it) is an element. In practice, one chooses basis functions, which are treated as known.

Assume that the function $f$ has a representation $f(x) = \sum_{j=1}^{k} b_j(x)\beta_j$, where $\beta_j$ are unknown parameters and $b_j(x)$ are known basis functions. Using a chosen basis for $f$ implies that we have a linear model $y = X\beta + \epsilon$, where the model matrix $X$ can be represented using basis functions such as those in the cubic regression spline basis. The departure from smoothness can be penalized with $\int f''(x)^2 dx$. The penalty $\int f''(x)^2 dx$ can be expressed as $\beta^T S \beta$, where $S$ is a coefficient matrix that can be expressed in terms of the known basis functions.

Accordingly, the penalized regression spline fitting problem is to minimise $\|y - X\beta\|^2 + \lambda \beta^T S \beta$, with respect to $\beta$. The problem of estimating the degree of smoothness is a problem of estimating the smoothing parameter $\lambda$. In the estimation, one faces a bias–variance trade-off: on the one hand, the bias should be small, but on the other hand, the fit should be smooth. One needs to compromise between the two extremes. $\lambda \to \infty$ results in a straight line estimate for $f$, and $\lambda = 0$ leads to an unpenalized regression spline estimate. The penalized least squares estimator of $\beta$, given $\lambda$, is $\hat{\beta} = (X^T X + \lambda S)^{-1} X^T y$. Thus, the expected value vector is estimated as $\hat{E}(y) = \hat{\mu} = A y$, where $A = X (X^T X + \lambda S)^{-1} X^T$ is called an influence matrix.

This setting can be augmented to include several covariates and smooths. Given a basis, an additive model is simply a linear model with one or more associated penalties. The size of basis dimension for each smooth is usually not critical in estimation, because it only sets an upper limit on the flexibility of a term. Smoothing parameters control the effective degrees of freedom, and the effective degrees of freedom can be used to measure the flexibility of a model. See Wood (2006) for more discussion.
